Outline

- **Introduction**
 - Heavy ion collisions and holographic shock-waves (very brief!)
- **Adding baryon charge** to the shock-wave collisions
 - **The model:** Einstein-Maxwell
 - **Shock wave collisions:** far from equilibrium full dynamic evolutions
 - **Results:** interpretation and comparison
- **Summary**

Introduction — Holographic shock-wave collisions

Heavy ion collisions

- Out of equilibrium quark-gluon plasma is created. Dynamic properties and collective behavior are studied.
- Striking observations: small shear viscosity and **fast hydrodynamization**.

Holographic shock-wave collisions

- Simple holographic toy models for collisions (**pure gravity** at first) **assuming very strong coupling**
- Very remarkable feature: reproduce **fast hydrodynamization!**
- Can we reproduce/predict more features (**baryon charge**)?

Introduction — Holographic shock-wave collisions

Simplest setup:

Pure gravity in 5d

corresponding to a 4d gauge theory

$$L = R + \frac{12}{L^2}$$

Lagrangian

$$R_{mn} + \frac{4}{L^2} g_{mn} = 0$$

Einstein's equations

The **metric** is dual to the **stress-energy tensor** operator of the gauge theory (not enough to capture baryon distribution!)

$$g_{mn} \longleftrightarrow \underline{T}_{ij}$$

If we know the **evolution of the metric** we know the dynamics of the plasma's pressures, energy density, fluxes. **We want more details: baryon current!**

Adding baryon charge — The model

Modified setup:

Einstein-Maxwell theory in 5d
corresponding to a 4d gauge theory
with a conserved **U(1) current**

$$L = R + \frac{12}{L^2} - \frac{1}{4} e^2 F_{mn} F^{mn}$$

Lagrangian

$$R_{mn} + \frac{4}{L^2} g_{mn} = e^2 L^2 T_{mn}$$

Einstein's equations

$$\partial_m (\sqrt{-g} F^{mn}) = 0$$

Maxwell's equations

The **metric** is dual to the **stress-energy tensor** operator
of the gauge theory

$$g_{mn} \leftrightarrow \underline{T_{ij}}$$

The **electromagnetic tensor** is dual to the conserved
U(1) current (that can be interpreted as **baryon current**)

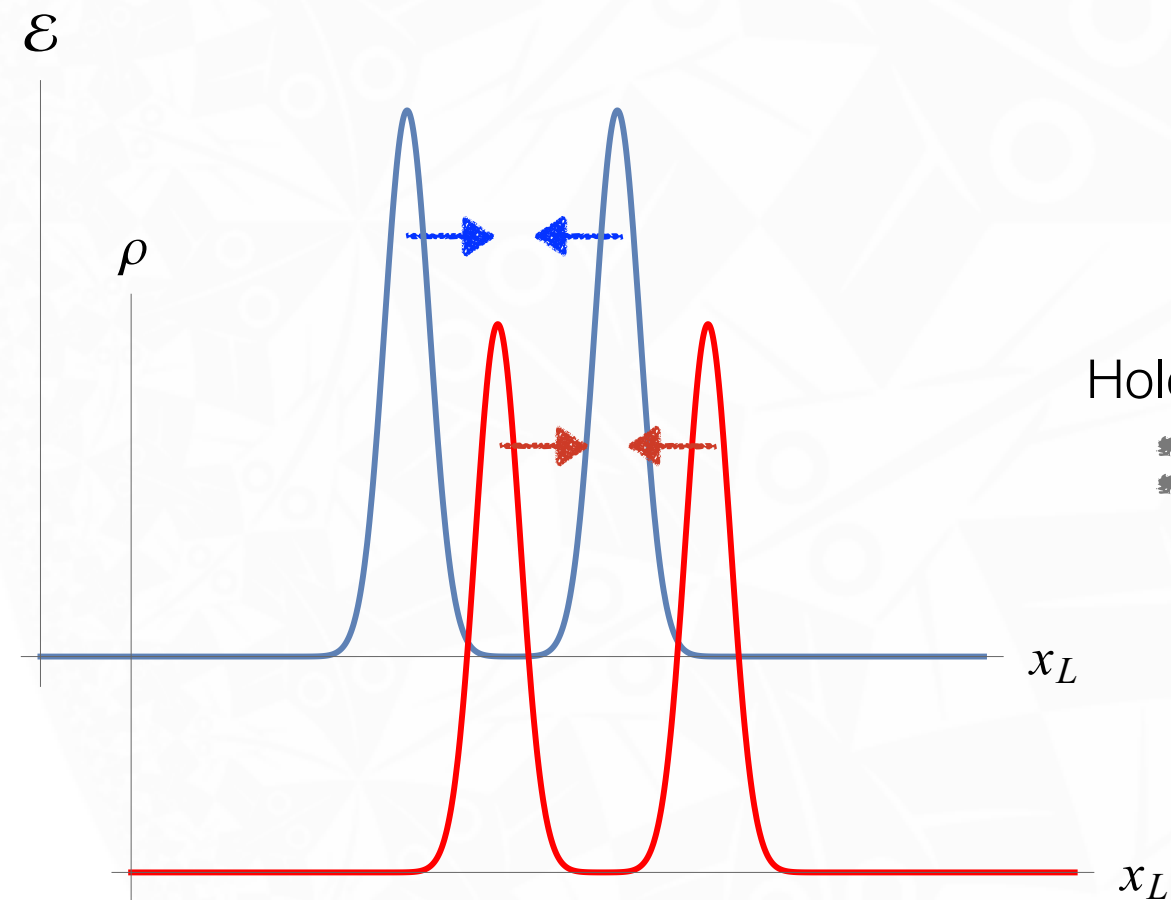

$$F_{mn} \leftrightarrow \underline{J_i}$$

If we know the **evolution of the electromagnetic tensor** we now know the
evolution and the distribution of **the “baryon” current**

Adding baryon charge — Shock-wave collisions

...One only needs an **initial state/geometry!**

Two infinite sheets of energy (and **“baryon” charge!**) colliding at the speed of light
(dynamics in 1 + 1 dimensions)

Holography

Traveling **“gravity-electromagnetic” waves**
(dynamics in 2 + 1 dimensions, holographic coordinate “u” and longitudinal “X_L”)

$$ds^2 = \frac{L^2}{u^2} (-dx_+ dx_- + d\mathbf{x}^2 + \underbrace{+ \left[u^4 h(x_+) - \frac{1}{3} e^2 u^6 a(x_+)^2 \right]}_{\text{In Fefferman-Graham coordinates}} dx_+^2 + du^2)$$

In Fefferman-Graham coordinates

$$A = \frac{u^2}{L^2} a(x_+) dx_+$$

In Eddington-Finkelstein coordinates

Adding baryon charge — Shock-wave collisions

Numeric implementation:

- Ingoing coordinates (Eddington-Finkelstein), **characteristic formulation**
- **Ultra-local in X_L longitudinal direction:** only needed to solve 1d ODEs in the “ u ” direction for each X_L point.
- Set of nested equations (Only first non-linear, some other linearly are coupled)

Example of a metric coefficient ($B[u, x_L, t]$)

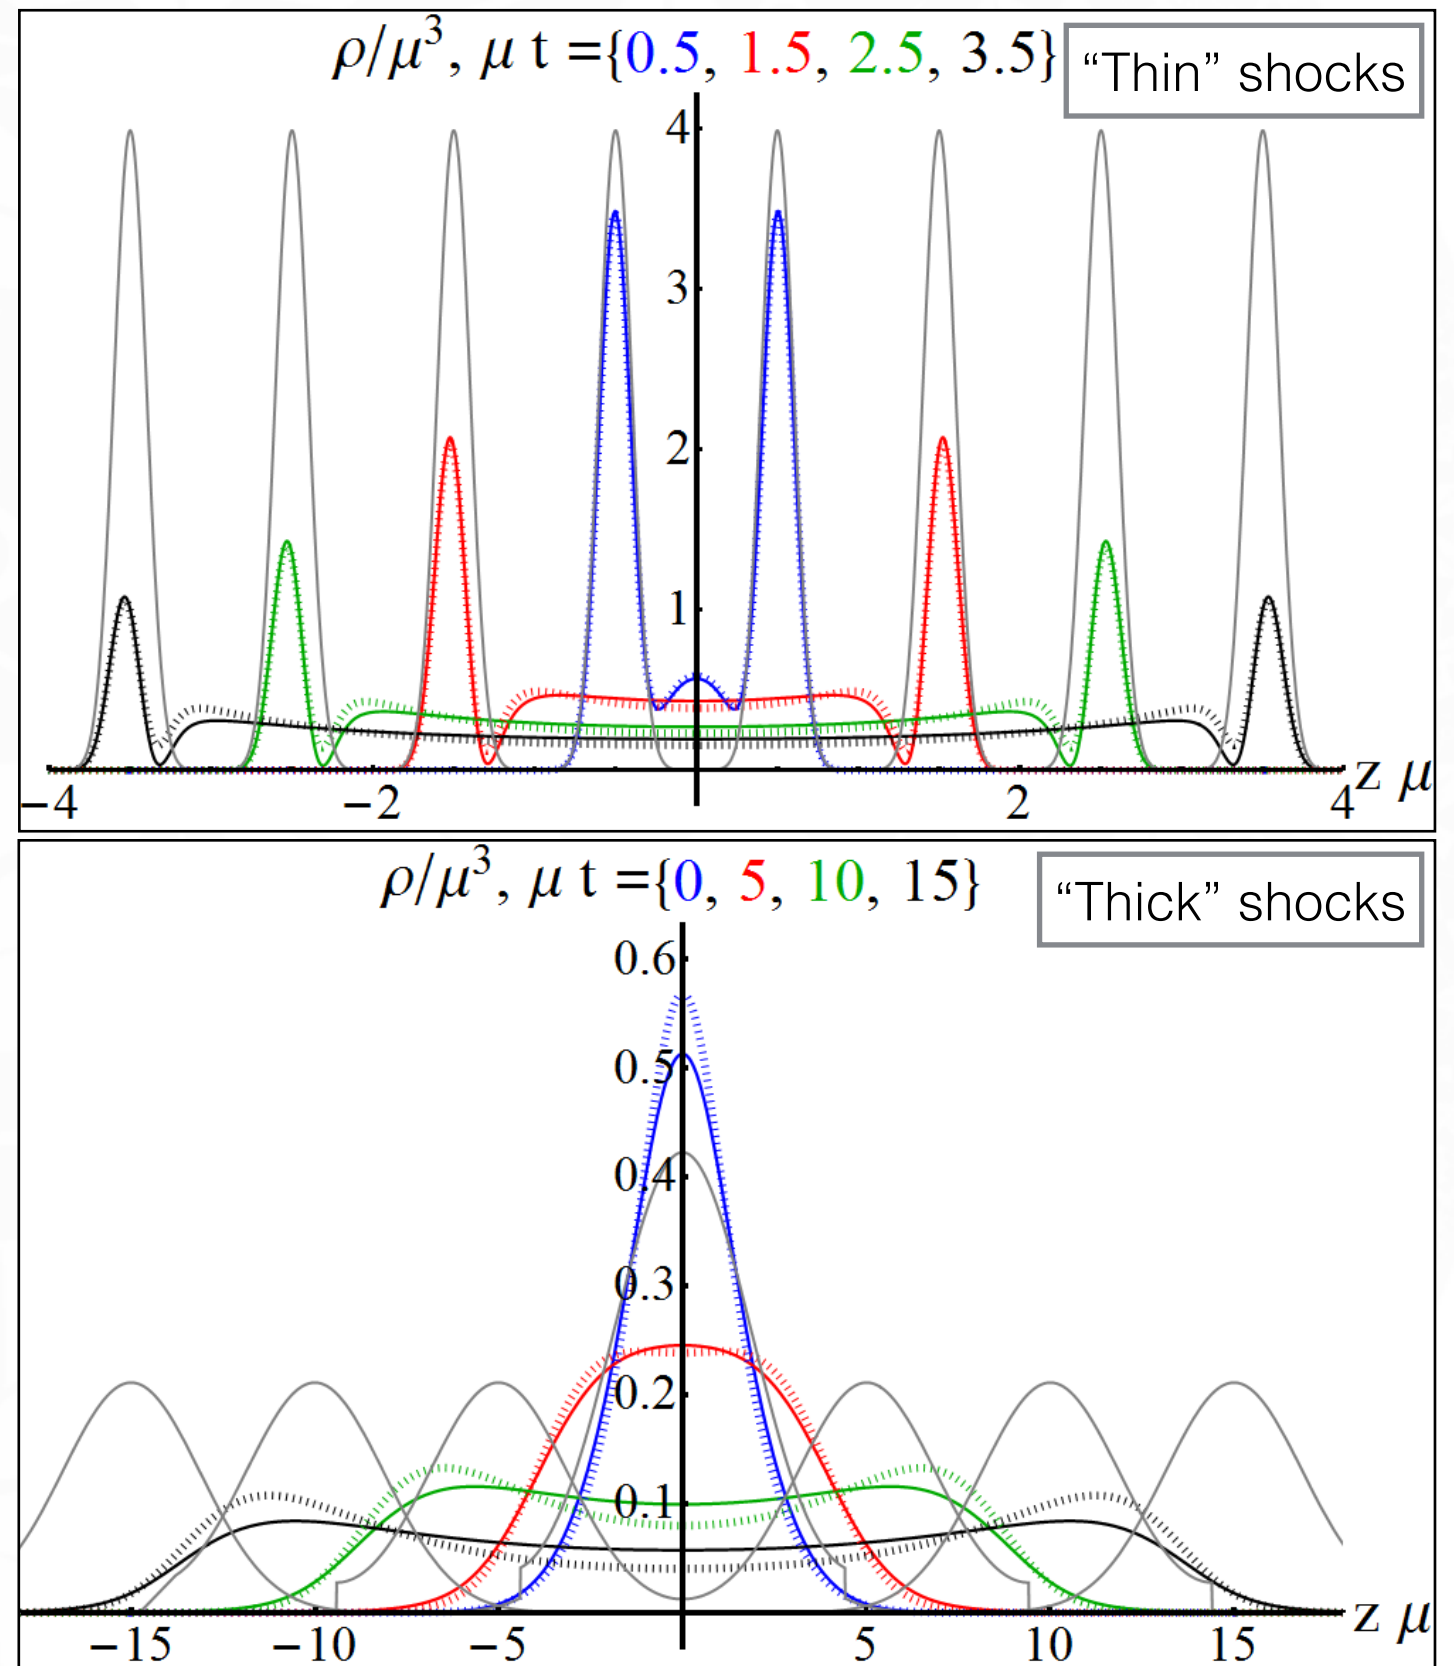

~500-1000 points in X_L direction (periodic)

Adding baryon charge — Results

Outcome

First we set $\mathbf{e} = \mathbf{0}$ (no backreaction):
energy remains the same as in pure grav.
We check “baryon” distribution.

- Behavior sensitive to initial width of the shock-waves (as pure grav.)
- Charge follows energy on the light-cone but does not at mid rapidities
- Lab frame does not show all the information (Lorentz effects)

Adding baryon charge — Results

Outcome

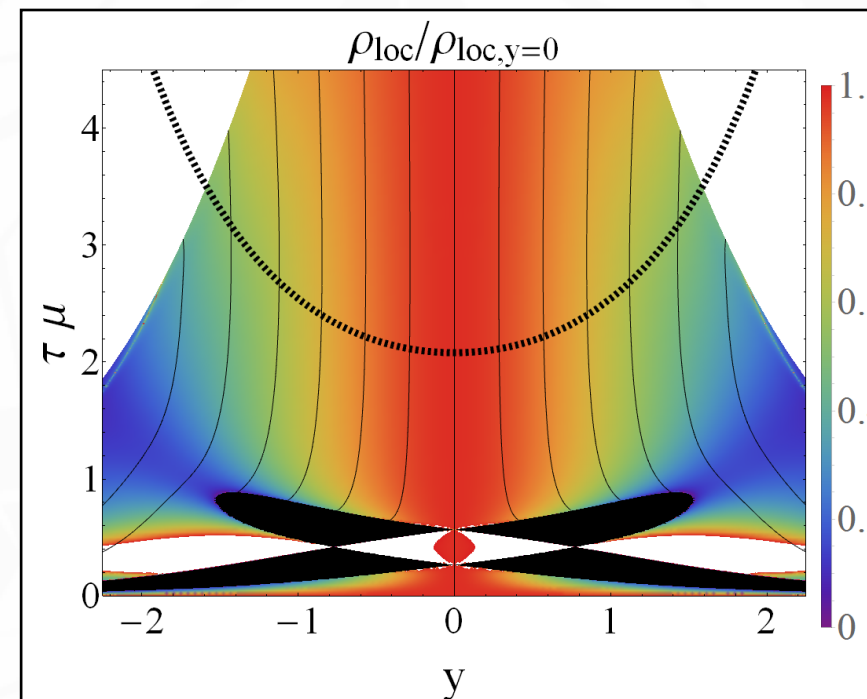

We check the **local rest frame** distributions **at constant proper time** (more relevant for freeze-out)

- Baryon content in plasma grows with proper time (non-boost inv.)
- Baryon charge distribution widens with proper time
- Hydrodynamic expansion pushes baryon charge towards large rapidities

“Thin” shocks

“Thick” shocks

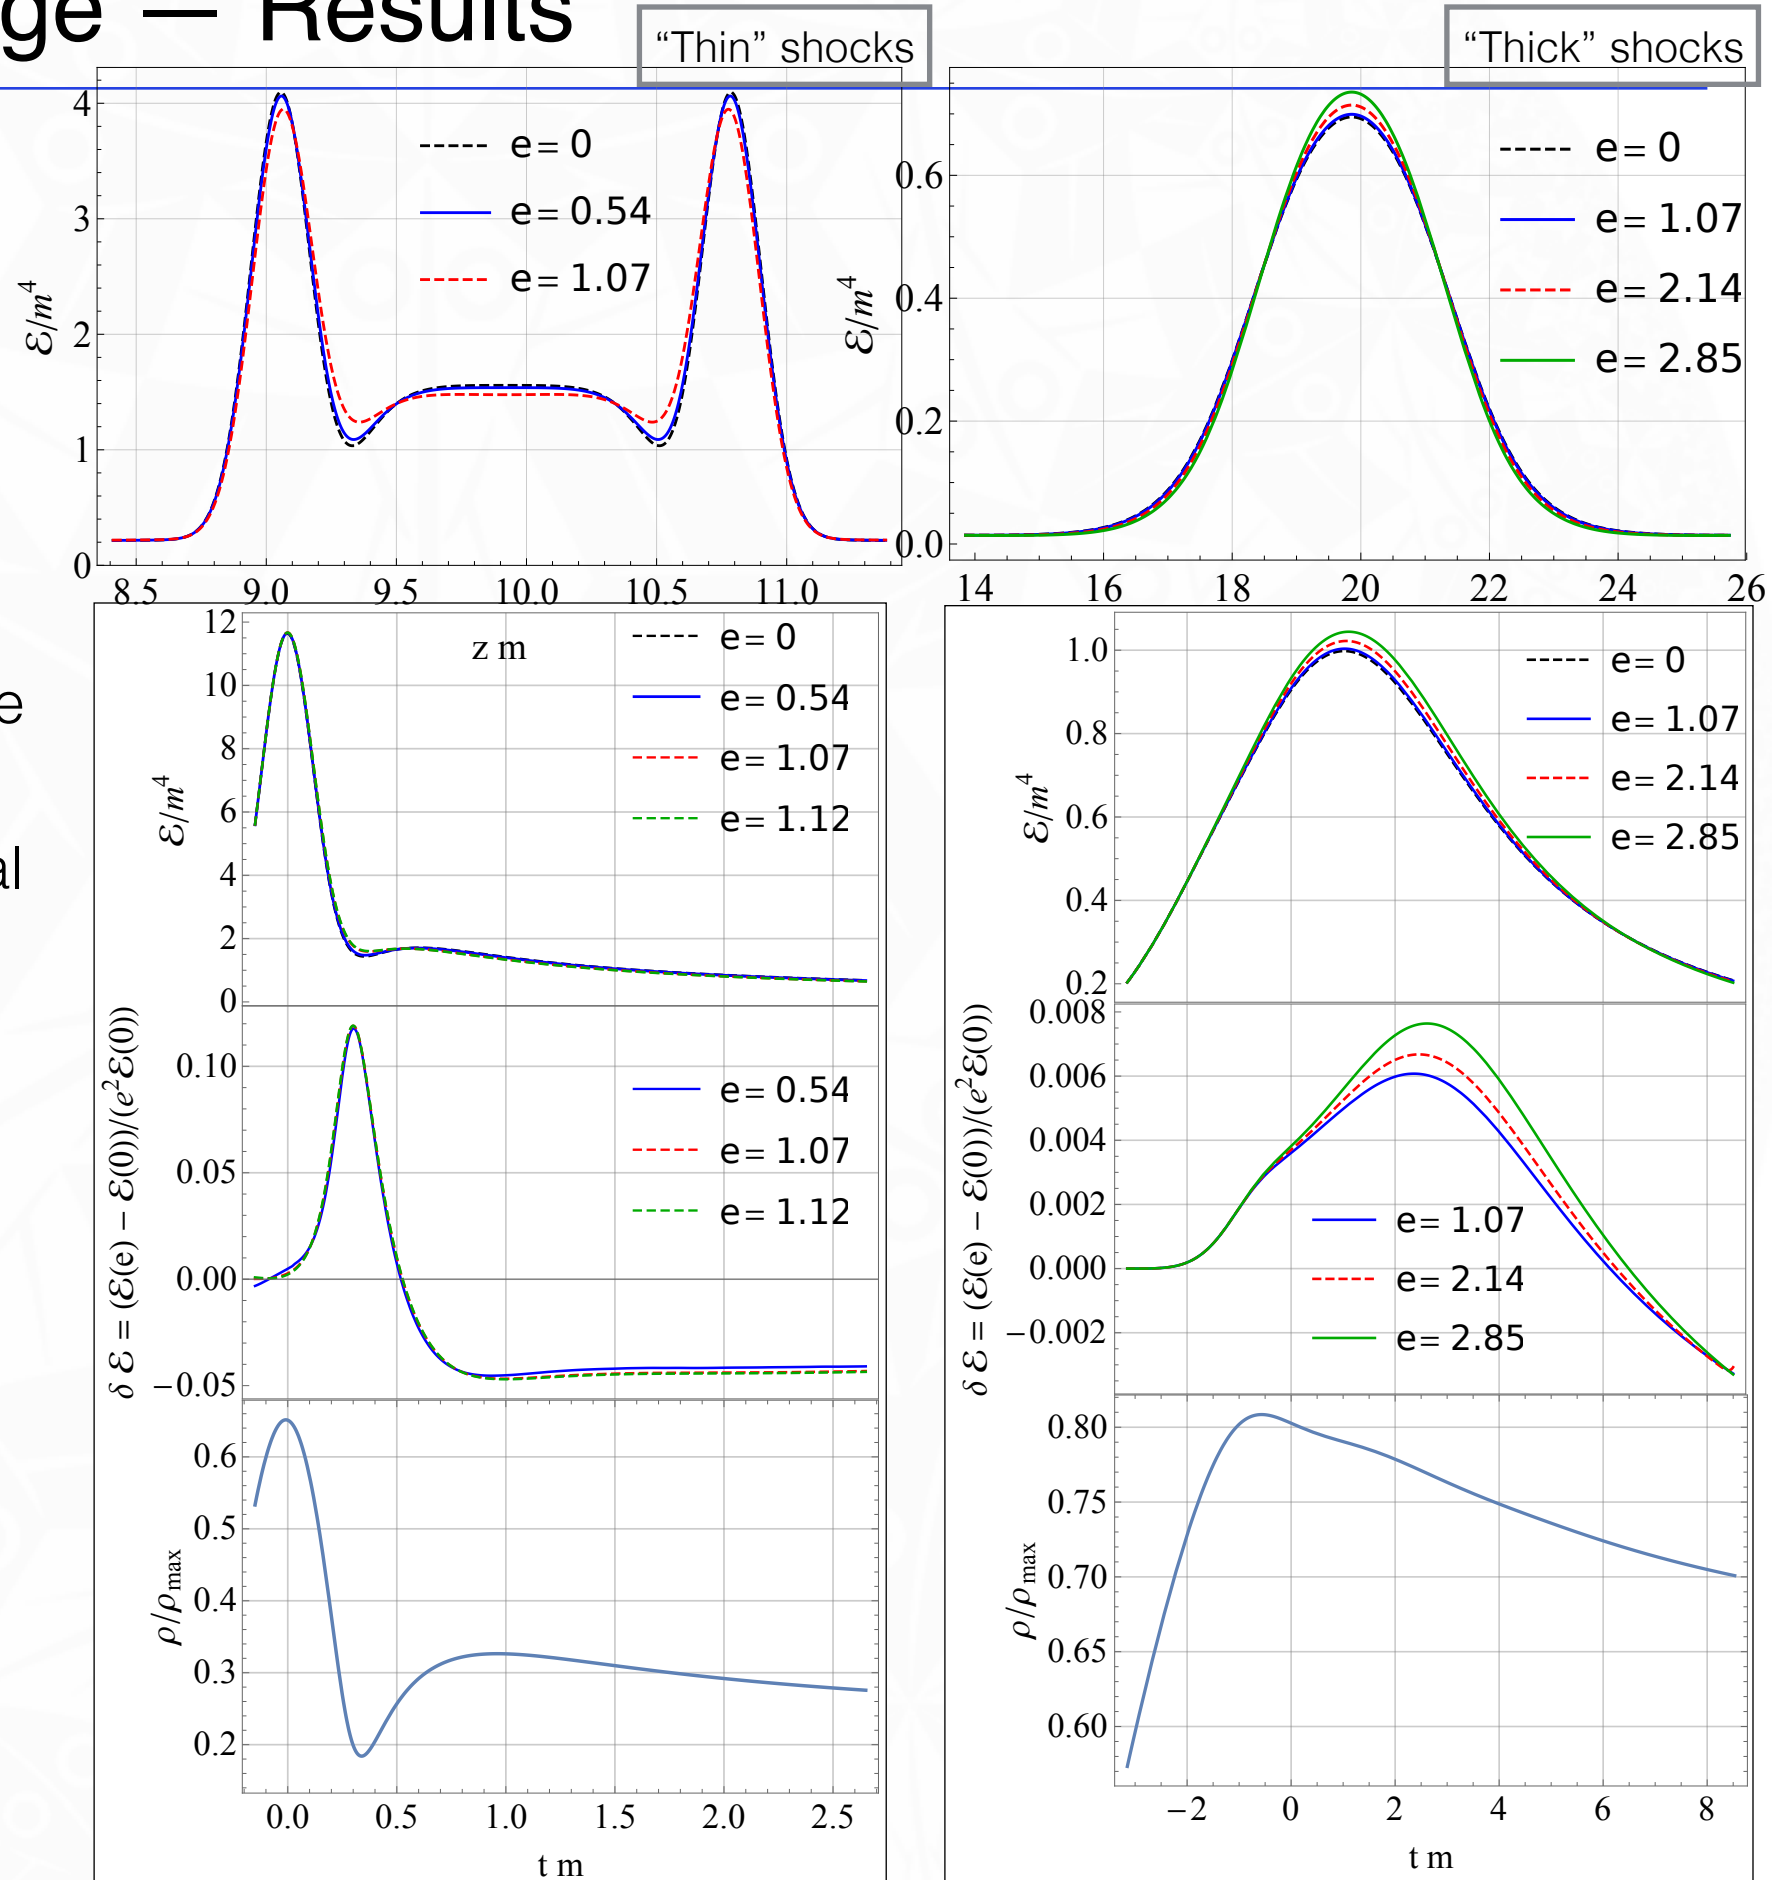

Adding baryon charge — Results

Outcome

Adding backreaction $e > 0$:
energy distribution is affected by
the baryon charge

- Effects of back-reaction moderate all the way up to maximum charge simulated (close to critical ratio?)
- Hydro time gets modified by a $\sim 3-5\%$
- Existence of two regimes: linear in e^2 , and non-linear

Adding baryon charge — Results

Outcome...How does compare to experiments?

Disclaimer: a proper comparison would require much longer run times and a proper freeze-out simulation.

Results seem to catch qualitative trend of low energy experiments (**AGS** or **SPS**)...

...However do not agree with high energy collisions at **RHIC** or **LHC**, as the fraction and not-so-high rapidities is small.

Plot from nucl-ex/0312023, BRAHMS Collaboration

Conclusion: our simple set-up is unable capture the weakly coupled physics at very high energies, nor the fine structure of the initial state involved in the dynamics of the collision.

Summary

- Plasma becomes more baryon rich with proper time. **Baryon charge is pushed towards higher rapidities** at later proper times.
- **Effects of back-reaction are small** all the way up to the maximum “e” values simulated. Two regimes: linear and non-linear.
- Simulations capture low energy experiments behavior but do not agree with the high energy ones. Limitations of setup and/or strong coupling?
